Abstract

We document a new set of facts regarding the impact of referrals on labor market outcomes. Our results highlight the importance of distinguishing between different types of referrals—those from family and friends and those from business contacts—and different occupations. Then we develop an on-the-job search model that incorporates referrals and calibrate the model to key moments in the data. The calibrated model yields new insights into the roles played by different types of referrals in the match formation process, and provides quantitative estimates of the effects of referrals on employment, earnings, output, and inequality.

Key words: labor markets, referrals, networks, search theory, asymmetric information
1 Introduction

According to surveys of workers and firms, a referral is used somewhere in the hiring process for approximately half of all jobs. Given its prevalence, this feature of job search is presumably an important channel for connecting workers with firms and helping to form matches. Moreover, as access to (and reliance on) referral networks tends to be heterogeneous across segments of the labor force, the use of referrals has the potential to generate or ameliorate economic inequality.

Despite the prevalence of referrals and their potentially important implications for labor market outcomes, it remains unclear exactly what (if anything) referrals actually do. While the theoretical literature has proposed a variety of channels through which referrals could play an important role in the match formation process, understanding and quantifying the effects of referrals has proven difficult, in large part because there are few representative datasets containing detailed information regarding the job search and/or hiring processes. Indeed, the existing empirical literature has found mixed evidence regarding even basic facts about referrals, such as the types of workers that use referrals most frequently or the effects of a referral on a worker’s starting wage.

The goal of this paper is to gain a better understanding of how referrals are used in the hiring process, and the quantitative implications for labor market outcomes, both at the individual level and in the aggregate. We proceed in three steps.

First, we exploit a novel dataset to establish a new set of facts about workers who used a referral in the process of forming their current match. Importantly, the data enable us to distinguish between different types of referrals—namely, those from family and friends and those from business contacts—and different types of jobs, as measured by the skill requirements of the occupation. Using these distinctions, we document clear patterns with respect to the frequency with which different types of referrals are used by workers in different occupations, and the subsequent wages and job turnover of workers who were referred by different types of contacts, relative to the non-referred.

Second, we develop a structural model to interpret our empirical findings. The model is carefully constructed to be rich enough to confront the facts we uncover in the data; flexible enough to accom-
moderate multiple, distinct theories of referrals; and yet tractable enough to solve by hand. Interpreting the data through the lens of the model turns out to be a crucial step in our analysis, as we ultimately identify key roles for unobserved heterogeneity and selection in explaining the endogenous relationships between a worker’s tendency to use different types of referrals and the worker’s subsequent labor market outcomes.

Finally, we combine our theoretical framework with key moments from the data to calibrate the model. This exercise reveals a number of qualitative insights into the distinct roles played by different types of referrals during the match formation process, as well as quantitative estimates of the contribution of referrals to employment rates, wages, turnover, earnings inequality, and output. We find that referrals from business contacts primarily screen workers based on their \textit{ex ante} expected productivity (or “type”), as in theories in which referrals ameliorate problems associated with asymmetric information about workers’ productivity. In the equilibrium of the calibrated model, we show that referrals from business contacts primarily help high productivity workers with high incomes, particularly in high skill occupations, and thus exacerbate earnings inequality. In contrast, we find that referrals from family and friends generate good matches independently of a worker’s type, as in theories where referrals improve match quality \textit{ex post}, perhaps by resolving symmetric uncertainty about match productivity or easing inefficiencies associated with moral hazard. The quantitative implication of this finding is that referrals from family and friends provide a key source of earnings for workers at the lower end of the income distribution, particularly in low skill markets, and thus tend to reduce earnings inequality. Thus, while both types of referrals are an important source of new and better matches, the oft-discussed trade-off between output and inequality only applies to referrals from business contacts; according to our quantitative exercise, referrals from friends and relatives increase output and reduce inequality.

We now describe each of the three steps described above, and the key insights that emerge, in greater detail. Then, we explain how these results fit into the existing literature.

\textbf{Facts.} As a first step, in Section 3 we document a number of new facts about the types of workers and occupations that tend to use referrals, and the characteristics of matches formed through a referral (relative to those formed through other channels). Our data, which come from a supplement to the Survey of Consumer Expectations, has a number of unique features that make it well-suited to study these issues: the survey draws from a wide range of demographic groups, industries, and occupations; it contains a rich set of information describing the job characteristics of currently employed workers; and, most importantly, it paints a detailed picture of the job search process that generated the current job (as well as other offers), including direct information about the use of referrals.

One particularly important aspect of the data is that it allows us to distinguish between referrals

\footnote{We discuss existing theories about the role of referrals in more detail in Section 1.1.}
from family and friends and those from sources we call “business contacts”. We find that the extent to which these two types of referrals are used differs substantially across occupations: referrals from family and friends are used relatively more frequently to find low-skill jobs, whereas referrals from business contacts are used relatively more frequently to find high-skill jobs. This suggests that the two types of referrals could be playing very different roles, and hence have different effects on observable outcomes.

In fact, the two types of referrals have opposing relationships with labor market outcomes. Workers who used a referral from a business contact tend to earn higher starting wages than non-referred workers, but experience shorter job tenures. Digging deeper, we find that this occurs because workers who got their current job using a business referral continue to meet other firms at a relatively high rate. In contrast, workers who used a referral from a friend or relative to get their current job tend to have lower starting wages than non-referred workers and experience less job turnover, because they receive offers at a relatively low rate.

Hence, the first part of the paper establishes that clear relationships emerge once we distinguish along two relatively unexplored dimensions of the data: the source of the referral, and the type of job or occupation. These relationships are not only suggestive about the different roles that the two types of referrals play in the hiring process, but they also help explain why previous studies—which could not make the same distinctions in the data—found mixed or conflicting results.

However, these empirical findings alone are insufficient to make substantive statements about the role of referrals in shaping labor market outcomes. Consider, for example, the positive relationship between the use of a business referral and a worker’s starting wage. Studying this bivariate relationship alone, one might be tempted to conclude that matches formed through business referrals are more productive, perhaps because referrals are an efficient technology for sharing information about idiosyncratic match quality. However, an equally plausible explanation is that (ex ante) more productive workers tend to use business referrals to find a job, perhaps because reputation concerns ensure that business contacts only refer “good” workers. Yet another possibility is that matches formed through business referrals are no more productive than matches formed through other channels, but instead workers who tend to use business referrals have better outside options (perhaps because they have larger networks of business contacts) and hence negotiate higher wages.

Distinguishing between these explanations is crucial for understanding both the qualitative role that these two types of referrals are playing in the search process and the quantitative contribution of each type of referral to observable outcomes, including employment rates, wages, inequality, and output. Therefore, in order to account for the endogenous nature of the empirical relationships we uncover, and to leverage the multiple, inter-related moments from the data, in Section 4 we construct a theoretical framework to interpret our empirical results.
Model. The key ingredients of the model are motivated by the patterns we observe in the data. First, given the clear correlations we find between various labor market outcomes and the channel through which a worker found a job, we allow for different technologies for initiating contact between workers and firms. In particular, we let contacts arrive through formal search methods, through referrals from business contacts, or through referrals from family and friends. Moreover, we allow the quality of the match (i.e., the match-specific productivity of a worker-firm pair) to depend on the channel through which the contact was initiated.

Second, since some workers appear to generate offers through different channels at different rates, even after controlling for a variety of observable characteristics, we allow for worker heterogeneity along some intrinsic type or “ability.” We allow a worker’s ability to affect both the (exogenous) rate at which the worker meets firms through different channels, along with the match-specific productivity they draw conditional on meeting a firm through a specific channel.

Finally, since a worker’s ability (or proclivity) to contact firms and generate offers does not evaporate after forming a match, but rather seems to be an important feature of understanding heterogeneity in wages and turnover, we assume that workers search when both unemployed and employed.

Our model can be seen as a natural extension of the workhorse models of on-the-job search with unobserved worker heterogeneity (Postel-Vinay and Robin [2002] Cahuc et al. [2006], extended to allow for multiple job search channels. The model is intentionally constructed to be rich enough to confront the facts we uncover in Section 3 yet equally as tractable as its predecessors. We exploit this tractability to derive closed-form expressions for key moments that we later target in the data, including the fraction of currently employed workers who used each job search channel to get their current job, and the average wage and tenure of currently employed workers conditional on the job search channel they used to form their current match. To the best of our knowledge, these derivations are new to the literature and offer at least two advantages when we take the model to the data. First, they allow us to calibrate the model without resorting to costly simulations. Second, and more importantly, they allow us to decompose key moments generated by the model, and thus better understand how the model is matching the data.

Calibration. Armed with a new set of moments from the data, and a model built to interpret these moments, in Section 5 we calibrate the model to uncover the values of the structural parameters required to generate the patterns we observe in the data. This exercise produces both qualitative and quantitative insights into the effects of referrals on labor market outcomes.

First, interpreting the data through the lens of our model reveals the underlying relationships between a worker’s unobserved type, the frequency with which he meets firms through different job search channels, the quality of these potential matches, and the implications for labor market outcomes. We find that a significant amount of heterogeneity in employment and earnings is driven by the fact that some types of workers are able to utilize referrals from business contacts to initiate
contact with a firm much more frequently than others. Referrals from family and friends, in contrast, are used more uniformly across worker types, and generate relatively high productivity matches, on average, conditional on a worker’s type.

These relationships reveal a number of insights into what role referrals play in the match formation process. On the one hand, the fact that business referrals are highly sensitive to a worker’s unobserved type—and, hence, her \textit{ex ante} expected productivity—suggests that referrals from business contacts are used primarily to screen workers, as in theories which ascribe a central role to a referrer’s ability to overcome problems associated with asymmetric information. Referrals from family and friends, on the other hand, appear most consistent with entirely different theories. More specifically, since referrals from family and friends tend to generate good matches independently of a worker’s underlying type, these types of referrals are most consistent with theories in which a referral improves match quality \textit{ex post}, perhaps by reducing symmetric uncertainty about idiosyncratic match quality or easing inefficiencies that derive from moral hazard.

In addition to revealing qualitative insights into the role of referrals in the labor market, the calibrated model allows us to quantify the extent to which (different types of) referrals affect employment, earnings, inequality, and output across workers in high- and low-skill labor markets. Interestingly, though referrals from family and friends have a negative correlation with wages in our regression analysis, we find that they are a crucial source of jobs for a certain subset of workers that struggle to generate offers and matches through more traditional channels. For example, in the low-skill labor market, we find that referrals from family and friends account for more than 15% of earnings and a 5 percentage point reduction in the unemployment rate of “low ability” workers. Hence, despite concerns that referrals based on nepotism may exacerbate earnings inequality, our findings suggest that referrals from friends and relatives are, in fact, an important force for reducing earnings inequality.

Referrals from business contacts, in contrast, are used more frequently by high ability workers—who also receive offers through other channels at a high frequency—and their contribution to earnings is more pronounced in high skill occupations. Again, these results highlight the importance of interpreting our data through the lens of a structural model. In particular, the positive relationship between the use of a business referral and wages alone might have suggested that referrals from business contacts help create relatively high quality, productive matches. Instead, our model reveals that an important aspect of business referrals is that they increase the wages of workers who have relatively good employment prospects to begin with. Hence, the use of business referrals, which is typically encouraged by firms, increases output but also exacerbates earnings inequality.

These findings suggest that the welfare implications of referrals may be more nuanced than would appear at first glance, and speak to the ongoing debate regarding the sources of economic inequality and the design of policies aimed at mitigating its adverse effects. Indeed, one potential implication of referrals from family and friends account for more than 15% of earnings and a 5 percentage point reduction in the unemployment rate of “low ability” workers. Hence, despite concerns that referrals based on nepotism may exacerbate earnings inequality, our findings suggest that referrals from friends and relatives are, in fact, an important force for reducing earnings inequality. These findings suggest that the welfare implications of referrals may be more nuanced than would appear at first glance, and speak to the ongoing debate regarding the sources of economic inequality and the design of policies aimed at mitigating its adverse effects. 5See also \textcite{Topa2019} and \textcite{Hellerstein2020} for a discussion of the implications of referrals for inequality.
our analysis is that it may be worth providing incentives to employers to tweak their employee referral programs in order to better target specific types of candidates, broaden their pools, and mitigate the “unintended consequences” of their programs with regard to earnings inequality. On the other hand, referrals from friends and family are sometimes viewed as an instance of nepotism, whereas our analysis suggests that they actually improve welfare for certain types of workers.

1.1 Related literature

Our paper contributes to the large (and growing) literature that studies the effects of referrals on labor market outcomes. For a broad overview of this literature, we refer the reader to the surveys by Ioannides and Datcher Loury (2004) and Topa (2011), and concentrate here on those studies most related to our work.

Early attempts to quantify the impact of using a referral focused primarily on deriving empirical estimates of the productivity, wages, and turnover of referred workers, relative to non-referred workers (see, for instance, the seminal work by Datcher (1983), as well as Corcoran et al. (1980), Green et al. (1995), Korenman and Turner (1996)). However, since referrals are typically not randomly assigned, these estimates are potentially driven by selection and unobserved heterogeneity, as opposed to capturing the direct effects of referrals. Broadly speaking, the literature has pursued two different approaches to overcome this challenge. First, a number of recent papers have exploited the availability of panel data and more sophisticated identification strategies to estimate the direct effects of referrals, including Bayer et al. (2008), Kramarz and Skans (2014), Schmutte (2015), Dustmann et al. (2016), Gee et al. (2017), and Heath (2018). Alternatively, a number of papers have used experimental settings to generate exogenous variation in the use of referrals; see, e.g., Bandiera et al. (2009), Beaman and Magruder (2012), Pallais and Sands (2016), and Friebel et al. (2019).

Our paper complements this strand of the existing literature in several important ways. The first derives from the unique nature of our data, which is drawn from a wide array of workers and occupations, and contains detailed information about the job search process, including direct information about the use of different types of referrals. Using these data, we are able to document a new set of stylized facts that highlight the heterogeneous impacts of referrals, as well as provide a novel explanation for conflicting results in earlier studies. Second, we account for the role of unobserved worker

\[6\] In contrast, most existing studies rely on data that either contains detailed information about job search methods or contains a representative sample of workers and/or occupations. For example, Brown et al. (2016), Burks et al. (2015), Castilla (2005), Heath (2018), and Marmaros and Sacerdote (2002) all contain direct evidence of whether a referral was used, but are drawn from workers in specific occupations, industries, or demographic groups. Alternatively, data collected from a more representative sample often does not contain information about how a worker-firm match was formed, forcing researchers to use proxies in the data that are likely to be correlated with (specific types of) referrals: for example, Bayer et al. (2008) and Schmutte (2015) use geographic clustering as a proxy for referrals, Dustmann et al. (2016) use ethnicity, Gee et al. (2017) use social media connections, Hensvik and Skans (2016) exploit overlap at a previous employer, and Kramarz and Skans (2014) use family relationships. However, unlike several of the datasets cited above, our dataset does not contain detailed information about firms, which limits our ability to control for firm fixed effects.
heterogeneity and selection by interpreting the relationships we observe in the data through the lens of a model. Using a large number of moments from the data, this allows us to recover key parameters of the model, which reveal new qualitative insights into the role of (different types of) referrals in the matching process, along with quantitative estimates of the contribution of (different types of) referrals to employment, earnings, inequality, and output.

Our paper also complements the large theoretical literature that develops models to understand how referrals ease certain frictions in the matching process, and the subsequent implications for labor market outcomes. For example, some theories posit that referrals reduce adverse selection, since a current employee can provide information about a prospective worker’s unobserved productivity (Montgomery [1991], Casella and Hanaki [2008], Galenianos [2014]). Other theories conjecture that referrals create good matches by reducing symmetric uncertainty regarding idiosyncratic match quality (Simon and Warner [1992], Dustmann et al. [2016], Brown et al. [2016], Galenianos [2013]). Still others propose that referred workers are more productive, *ex post*, because the referrer can monitor the new worker or serve as a mentor (Kugler [2003], Castilla [2005], Beaman and Magruder [2012], Heath [2018]). Finally, some models attribute the primary role of referrals to reducing search frictions by making workers better aware of existing vacancies (Holzer [1988], Topa [2001], Galeotti and Merlino [2014], Galenianos [2014], Schmutte [2015]).

In contrast to these papers, we use a model that does not derive specific microfoundations for a particular theory of referrals. Rather, we adopt a more flexible, reduced-form approach, and let the data dictate the relationship between, e.g., a worker’s underlying type, the rate at which she meets firms through different channels, the quality of the matches generated through each of these channels, and the subsequent effects on wages and turnover. By being *ex ante* agnostic about the specific mechanisms, the model remains rich enough to accommodate and identify the distinct properties of referrals from different sources. As a result, our paper sheds light on which of the theories cited above are most consistent with the empirical evidence regarding the relationship between different types of referrals and labor market outcomes across occupations.

Finally, our work is also closely related to several recent papers that study the impact of referrals on labor market outcomes by combining theoretical models of referrals with data containing detailed information on workers’ job search methods. Perhaps most closely related to our work is [Arbex et al. (2019)] and the contemporaneous paper by [Moon (2021)], both of which construct on-the-job search models and calibrate these models to data from the Survey of Consumer Expectations. Despite these broad similarities, the focus of these two papers is much different from our own. [Arbex et al. (2019)] develop a model with a rich network structure and focus exclusively on heterogeneity in workers’ access to business referrals. Like us, they find that this unobserved heterogeneity across workers is an important source of dispersion in employment status and earnings. However, their focus is more on the impact of network structure and connectedness, while we focus more on the distinct qualitative and quantitative effects of referrals from different sources across different occupations. [Moon (2021)]
concentrates on developing explicit microfoundations for one particular theory of referrals—namely, he models the strategic incentives of a referrer to provide firms with an accurate signal of match-specific productivity. Consistent with our findings, his model predicts that referrals from business contacts should be associated with higher wages.  

2 Data

We use data from a supplement to the Survey of Consumer Expectations (SCE), which is administered by the Federal Reserve Bank of New York. The SCE is a nationally representative, monthly online survey of a rotating panel of about 1,300 household heads. New respondents are drawn each month to match various demographic targets from the American Community Survey (ACS), and they stay on the panel for up to twelve months. The supplement we use, called the Job Search Survey, has been administered annually since 2013.

This dataset is particularly well-suited to our objectives in several dimensions. First, the survey asks a broad range of questions regarding how employed workers found their current job. Second, it asks about many different characteristics of the job including wages, benefits, job tenure, job satisfaction, and job search behavior. Third, since it is a representative survey it covers workers across a wide range of individual characteristics and occupations. In addition to detailed information about the current job of the worker, our dataset also contains information about respondents’ previous work experience, along with all of the usual demographic information contained in the SCE data.

Our analysis focuses on non-self-employed individuals aged 18 – 64. This leaves us with a sample of about 5,000 observations covering the years 2013-2018. See Appendix A for additional details about how we generate some of our variables and arrive at our final estimation sample.

2.1 Construction of key variables

Before presenting our empirical results, we describe how we construct two key variables related to the source of the referral (business versus family/friends) and the skill content of the job.

First, to determine whether a worker used a referral, and the type of the referral, we rely on a question from the survey that asks currently employed workers how they “learned about their current job”. Using the worker’s response to this question, we construct binary indicators for two types of referrals: (i) family or friend, and (ii) business contact. Since individuals are allowed to give multiple

---

7Another recent, related paper is [Caldwell and Harmon (2019)], who estimate a structural on-the-job search model using matched employer-employee data from Denmark. In contrast to our paper, they use a worker’s network of contacts as a source of variation in outside options to study the relationship between bargaining power and wages. They find that an increase in information about job openings—coming from closely connected former co-workers employed in other firms—leads to higher mobility and wage growth.

8The survey was designed by Jason Faberman, Andreas Mueller, Ayşegül Şahin, and Giorgio Topa. See [Faberman et al. (2017)] for a more detailed description of the survey and associated dataset.
responses to this question, these measures are not mutually exclusive. For those that indicated they were “referred by a friend or relative,” we set the indicator for referral from family and friend equal to 1, and 0 otherwise. For referral from business contacts, we set the indicator equal to 1 if the individual responded that they were “referred by a former co-worker, supervisor, business associate”. We also set the business contacts indicator equal to 1 if they reported being “referred by a current employee at the company,” as long as they did not also indicate that they were referred by a friend or relative. In other words, if a worker who indicated that they were referred by a friend or relative also indicated that they were referred by a current employee at the company, we classify this as a referral from a family member or friend, as it seems most likely that the two answers correspond to the same referrer. However, if the worker responded that they were referred by a current employee at the firm but not by a friend or relative, we classify the referrer as a business contact.9

Second, to classify different types of jobs, we measure the skill content of each (employed) worker’s reported occupation using the Nam-Powers-Boyd (NPB) occupational index. This index ranks occupations (at the 3-digit occupation level) based on the earnings and educational levels of the workers in each occupation.10 To do so, one first calculates the median education level and median earnings of individuals in each occupation. Then, these values are weighted by the number of people in each occupation to create a percentile measure of the position of each occupation in both the education and earnings distributions. Finally, these two percentiles are averaged to generate the index. Scores can range from 0 to 100.11 The version we use comes from 2016 and is based on data from the American Community Surveys from 2010-2012, accessible via IPUMS.12

To give the reader a sense of the NPB occupational index, Table 1 provides a list of NPB scores assigned to various occupations, aggregated at the 2-digit occupation level for the sake of presentation. One can see that scores range from 0 to 100, with “Food Preparation and Serving Related Occupations” (FOOD) at the bottom and “Legal Occupations” (LEGL) at the top. Note that each of these groups is a weighted average of scores at the 3-digit occupation level; for example, FOOD contains both “chefs and head cooks” (NPB score of 40) and “dishwashers” (NPB score of 1), while LEGL contains both “lawyers, judges, and related workers” (NPB score of 99) and “paralegals and legal assistants” (NPB score of 70). For all of our regression analysis below, we use the finer, 3-digit occupation scores.

9 Using this method of classification, about 8% of referred workers have both referrals indicators equal to 1. We experimented with several ways of dealing with the overlap between the two measures, including fully partitioning the three responses related to referrals, and our empirical results did not change significantly.

10 Occupations in the SCE are categorized using the Standard Occupational Classification System (SOC) from the Bureau of Labor Statistics (BLS).

11 We also experimented with an alternative occupation index constructed using O*NET data. Specifically, the measure was computed as the fraction of jobs within an occupation code that require a bachelor’s degree, which generated scores that also ranged from 0 to 100. Results were qualitatively similar using this alternative measure.

12 The NPB scores are available for download at http://www.npb-ses.info/.

3 Empirical Results

In this section, we examine the frequency with which the two different types of referrals are used across occupations, and the characteristics of matches formed using each type of referral. Since our indicators of usage are derived from currently employed workers, our estimates in this section are based on the sample of workers who were currently employed at the time of the survey. Note that in Section 5 when we calibrate our model to a larger set of moments, we will use the full sample of employed and unemployed workers.

3.1 Usage of Referrals Across Occupations

We first examine the relationship between the usage of the two types of referrals and the skill requirements of different occupations. As a first step, Figure 1a plots, for each 2-digit occupation code, the percentage of currently employed workers who report having used a referral from a family member or friend in the process of being hired at their current job. Figure 1b plots the corresponding relationship for business referrals. The figures suggest that referrals from family and friends are used more often in the formation of low-skill jobs, while referrals from business contacts are used relatively more often in the formation of high-skill jobs.

Figure 1: The Use of Referrals Across Occupations

(b) Referrals from Business Contacts

Notes: This figure plots the fraction of individuals within each 2-digit occupation that found their current job through a referral from family and friends (panel a) and from a business contact (panel b) against the skill content of the job (NPB score). The size of each dot is proportional to the number of individuals within each occupation.

Of course, these patterns could reflect differences in the characteristics of the workers in these occupations, and not necessarily differences in the occupations themselves. To establish that this relationship is not just capturing worker characteristics, we run a linear regression on a dummy variable for referral usage (for each type of referral) against the skill index of the occupation, time and geo-
graphic region fixed effects, and a rich set of worker characteristics. These characteristics include age, gender, race, marital status, number of children under the age of 6, and home ownership status. Table 2 confirms that there is a positive relationship between the use of business referrals and occupational skill, and a (stronger) negative relationship between the use of referrals from family and friends and occupational skill.

Notes: Estimates are from regressions in which the outcome is whether an individual used either a business or family/friend referral to find their current job. Individual controls include age, gender, race, marital status, number of children under the age of 6, and home ownership status. Standard errors are presented in parentheses below the point estimates. *** denotes significance at the 1% level, ** denotes significance at the 5% level, and * denotes significance at the 10% level.

The patterns we document in Figure 1 (and Table 2) suggest that referrals from family and friends and referrals from business contacts might be playing different roles (or helping to overcome different frictions) in the matching process. This observation prompts two conjectures. First, if the two types of referrals are playing different roles, then one might naturally expect them to be associated with different labor market outcomes. Second, if the mix of referrals from family and friends and business contacts varies across occupations—and referrals from these two sources have different effects on labor market outcomes—then one would also expect that two studies focusing on different occupations or sectors may find conflicting results regarding the relationship between labor market outcomes and the use of any type of referral.

We now explore these conjectures in the data. In particular, we examine the relationship between the use of referrals and two standard measures of labor market outcomes: wages and tenure. We show that clear and opposing relationships emerge, but only after conditioning on the two types of heterogeneity highlighted above—namely, different types of referrals and different types of occupations.

For ease in interpretation we employ a linear probability model for all of our binary outcomes. However, results are very similar using a logit or probit specification.

In the regressions, we use the skill index for the more detailed 3-digit occupation code. However, the results remain similar if we use the more aggregated 2-digit occupation code, as in Figures 1a and 1b above.
3.2 Referrals and Starting Wages

We first study workers’ starting wages. In column (1) of Table 3, we report results of a regression of log (real) starting wages on dummy variables that indicate whether the worker used a referral from a business contact or family/friend in the hiring process. Again, we control for time and region fixed effects, as well as observable worker characteristics. We find that workers referred to their current job by a business contact have starting wages that are approximately 16% higher than non-referred workers, while those referred by family and friends have starting wages that are approximately 9% lower than the non-referred. In column (2), we control for the skill index of the worker’s occupation. The coefficient on business referrals is essentially unchanged, while the coefficient on referrals from family and friends decreases in absolute value, but remains negative and statistically significant.

Notes: Estimates are from regressions of the log of the real starting wage for the worker’s current job. Individual controls include age, gender, race, marital status, number of children under the age of 6, and home ownership status. Standard errors are presented in parentheses below the point estimates. *** denotes significance at the 1% level, ** denotes significance at the 5% level, and * denotes significance at the 10% level. There are 462 observations for which we do not observe the starting wage. We lose 1006 observations when adding previous wage as a control due to missing data on previous wage. Results for the specifications without previous wage as a control (columns 1, 2, 4, and 5) are similar when using this more restricted sample.

In column (3), we also control for the previous wage in an attempt to control for unobserved worker heterogeneity. Not surprisingly, there is a strong positive relationship between the wage at the previous job and the starting wage at the current job. Moreover, while the coefficient on business referrals remains positive and statistically significant, the coefficient on referrals from family and friends becomes small and insignificant. As we discuss in more detail below, these findings are
consistent with a selection effect; that is, referrals from family and friends do not necessarily cause lower wages, but rather these types of referrals tend to be used by workers who earn lower starting wages because of characteristics not easily observed by the econometrician. For example, the results in column (3) are consistent with an environment in which workers who use referrals from family and friends have fewer outside options than otherwise similar workers, and hence receive lower wages.

In columns (4)–(6), we report results for the same regressions without distinguishing between the two types of referrals, i.e., we regress starting wages on a dummy variable that takes value 1 if the worker used any type of referral. We find that the relationship between the use of a referral and starting wages disappears. This insight—that referrals from business contacts and family/friends are associated with opposing effects on starting wages—may help to explain why the existing literature has found mixed evidence regarding the relationship between wages and referrals.

### 3.3 Referrals and Job Tenure

We now analyze the relationship between the use of referrals and job tenure. We measure the job tenure of all currently employed workers at the time of the survey using data on the start date of each worker’s current job. Ideally one would like to analyze the duration of completed employment spells, but this is not possible given the repeated, cross-sectional nature of our data. Despite the potential limitations of our stock-sampled measure of job tenure, we believe that results based on this measure are still informative about the relative tenures across different types of referrals and occupations, particularly given the large differences we find. As a robustness check, we use our quantitative model to directly compare stock-sampled spells to completed spells, and we find that two measures deliver very similar results regarding the differences in tenure across job search method.

In Table 4, we regress job tenure on the dummy variables for referrals, using the same set of controls described above. Columns (1)–(3) show that workers who were referred by business contacts have significantly shorter job durations than the non-referred, while those who were referred by family and friends have significantly longer durations. Note that the result for business referrals would be considered surprising within the context of theories with symmetric uncertainty regarding match-specific productivity (a la Jovanovic [1979]), since such theories typically predict a positive relationship between match quality, wages, and job tenure. Indeed, columns (4)–(6) suggest that one would actually find a positive (although not precisely estimated) relationship between the use of any referral and job tenure in our data. However, much like our results on wages and referral usage, these

---

15Workers are only tracked for a period of one year in the SCE, and thus we observe very few completed job spells.
16As is well known, data like ours—which is left-truncated and right-censored—suffers from competing biases. On the one hand, since it is left-truncated, workers with shorter spells are less likely to be sampled. Hence, our measure of average tenure overestimates the average tenure of length spells. On the other hand, since it is right-censored, our measure of average tenure underestimates the average length of completed spells. Under certain assumptions (see, e.g., Heckman and Singer [1984]), these biases cancel and the average job duration that we observe is a consistent estimate of the true, uncensored duration.
regressions would be misleading, since they mask stark differences between the effects of referrals from business contacts and those from family and friends.

Notes: Estimates are from regressions of the log of the duration of the current job. Individual controls include age, gender, race, marital status, number of children under the age of 6, and home ownership status. Standard errors are presented in parentheses below the point estimates. *** denotes significance at the 1% level, ** denotes significance at the 5% level, and * denotes significance at the 10% level. We lose 1303 observations when adding previous wage as a control due to missing data on previous wage. Results for the specifications without previous wage as a control (columns 1, 2, 4, and 5) are similar when using this more restricted sample.

What generates these patterns? There are many reasons why matches formed through different channels may last for longer or shorter periods of time. For example, if relatives and friends have superior knowledge about a worker’s preferences or personal circumstances, then matches formed through family and friends could be “better” along non-pecuniary dimensions, such as flexible hours, non-wage benefits, or the potential for faster advancement, which would explain why workers who match through this channel tend to stay at their job longer. However, we do not find any evidence suggesting a relationship between the use of referrals and job satisfaction or “fit.” In particular, in Appendix A, we exploit several questions from the survey on job satisfaction to document that workers hired through either type of referral are no more or less satisfied with various aspects their job than non-referred workers.\(^{17}\) Consistent with this evidence, we also show that workers hired through either type of referral are no more or less likely to be currently looking for a new job, relative to non-

\(^{17}\)As we discuss in detail in the Appendix, workers are asked about their overall satisfaction, their satisfaction with their compensation, the “fit” of the job, the opportunities for promotions or other career progression, and their satisfaction with other, non-wage aspects of the job.
referred workers. We also examined wage growth and found no significant differences across job finding method.

Instead, the difference in job tenure appears to be driven by different arrival rates of outside offers after being hired into their current job. Table 5 reports the output of a linear regression model where the dependent variable is an indicator for whether a currently employed worker has had at least one contact with another firm in the last four weeks. As is evident, workers who got their current job through a business contact are significantly more likely to make contact with additional firms than non-referred workers, whereas those who were hired through a referral from a family member or friend are significantly less likely to have generated new contacts in the past four weeks.\footnote{We test other horizons as well, and find similar results.}

### 3.4 Summary of Facts and Key Ingredients for a Model

In this section, we established that the frequency with which different job search channels are used varies systematically across occupations, and that worker-firm matches formed through different job search channels are associated with significant differences in labor market outcomes. In particular,
business referrals are used relatively more frequently at high skill jobs and are associated with higher starting wages but shorter tenures, as workers hired through business referrals continue to receive offers at a high rate after forming a match. In contrast, matches formed with the help of family and friends occur relatively more frequently at low skill jobs and are associated with lower starting wages, though this difference vanishes when controlling for unobserved worker heterogeneity (through previous wages). Still, despite earning relatively low wages, workers who are hired through family and friends tend to stay longer at their job, as they receive new opportunities less frequently than others.

In the next section, we use these facts to guide the construction of a structural model of the labor market. The model has three key ingredients. First, we assume that matches between workers and firms can be formed through three distinct channels: a referral from family and friends, a referral from a business contact, or other (formal) job search channels. Second, since workers in our data appear to generate offers through these different channels at (persistently) different rates, even after controlling for a variety of observable characteristics, we introduce unobserved worker heterogeneity. Importantly, we allow the rate at which workers meet firms through the different job search channels and the quality of the matches they form to depend on their unobserved type or “ability.” Third, since workers’ (heterogeneous) abilities to generate offers does not vanish after forming a match, we assume that workers search both off and on the job.

4 Model

We incorporate multiple job search channels into the workhorse model of on-the-job search with unobserved worker heterogeneity, as formulated by Postel-Vinay and Robin (2002) and Cahuc et al. (2006). In fact, as we establish below, if one aggregates these multiple channels into a single matching technology, the equilibrium is essentially the same as that in Cahuc et al. (2006). For this reason, we keep the characterization of standard equilibrium objects brief, and instead focus on the novel aspects of our framework—namely, the ability to study the behavior of wages and mobility conditional on the channel that the worker used to find his current job. In particular, using techniques from Hugonnier et al. (2020), we are able to derive analytical expressions from our model corresponding to all key moments from the data (channel-specific and otherwise). Hence, our approach for integrating multiple job search channels generates a rich framework capable of confronting the facts that we uncovered in Section 3, with essentially no loss in tractability.

4.1 Environment

We consider a continuous time, infinite horizon environment in which all agents are risk neutral and discount the future at rate $r > 0$. There is a measure 1 of workers who are heterogeneous with respect to their ability, which we denote by $a \in A \equiv \{a_1, \ldots, a_N\}$ for some $N \in \mathbb{N}$. We let $\pi_i$ denote
the fraction of workers with ability \( a_i \), with \( \sum_{i=1}^{N} \pi_i = 1 \). As we discuss in more detail below, a worker’s ability \( a_i \) should not be confused with their skill or occupation: when we take the model to the data, we interpret each occupation or skill level as a separate labor market, and interpret \( a_i \) as the unobservable ability of workers within that market.\[19\]

There is a large measure of firms that operate a constant returns to scale production technology. When a worker meets a firm, the pair draws a match-specific productivity \( x \in [\bar{x}, \overline{x}] \). If they choose to form a match, the worker and firm jointly produce a flow amount \( f(x) = px + c \) for some \( p \in \mathbb{R}_+ \) and \( c \in \mathbb{R} \). An unmatched (unemployed) worker consumes a flow amount \( b \), while an unmatched vacancy at a firm produces 0. Worker-firm matches are exogenously destroyed at rate \( \delta \).

Meetings. The first key departure from the existing literature is that we assume contacts or “meetings” between workers and firms occur through one of three channels: a referral from a family member or friend; a referral from a business contact; or formal (“other”) channels. We denote these by \( F, B, \) and \( O \), respectively, and denote the set of possible channels by \( \mathcal{C} \equiv \{F, B, O\} \).

The second important departure from the existing literature is that we assume a worker’s type can affect the rate at which he meets firms through the various channels. In particular, we assume that employed and unemployed workers of ability \( a_i \) generate meetings through channel \( j \in \mathcal{C} \) at rate \( \lambda_j^e(a_i) \) and \( \lambda_j^u(a_i) \), respectively. Conditional on meeting, a match-specific productivity is then drawn from a distribution with cdf \( H_j(x|a_i) \). It will be convenient to define

\[
\Gamma_j^k(x|a_i) = \lambda_j^k(a_i) \bar{H}_j(x|a_i)
\]

for \( j \in \mathcal{C} \) and \( k \in \{e, u\} \), where \( \bar{H}_j(x|a_i) \equiv 1 - H_j(x|a_i) \). In words, \( \Gamma_j^e(x|a_i) \) is the arrival rate of offers for an employed worker of ability \( a_i \) through channel \( j \) with a match-specific productivity that exceeds \( x \). It will also be convenient to define the arrival rate of such contacts through any channel by

\[
\Gamma^k(x|a_i) = \sum_{j \in \mathcal{C}} \Gamma_j^k(x|a_i), \quad k \in \{e, u\}.
\]

This specification allows a worker’s type to affect both the arrival rate of meetings and the idiosyncratic quality of the match. This modeling choice, while reduced-form, is meant to encapsulate a variety of micro-founded theories of job referrals (discussed in the literature review), as some theories focus on the role of referrals in generating meetings for (at least some types of) workers, while other theories focus on the quality of matches formed through referrals.

\[19\]In other words, our model could be interpreted as the market for high skill workers—say, lawyers—and ability \( a_i \) distinguishes good from bad lawyers.
**Wage Determination.** To close the model, we assume that wages are determined by the strategic wage bargaining protocol described in [Cahuc et al. (2006)](#). According to this protocol, when an unemployed worker meets a firm and there are gains from trade, the firm and the worker bargain over the wage as in standard models (e.g., [Mortensen and Pissarides, 1994](#)). We let $\beta$ denote the share of the surplus that the worker receives, or the worker’s “bargaining power”.

When an employed worker meets a new firm, a three-player bargaining game ensues. If the match-specific productivity at the poaching firm ($x'$) is greater than the match-specific productivity at the incumbent firm ($x$), then the worker moves to the poaching firm and the two parties determine the wage by bargaining over the match surplus, where again $\beta$ denotes the worker’s bargaining power. To derive this match surplus, we define the worker’s outside option (of not moving to the poaching firm) as remaining employed at the incumbent firm at a wage equal to his marginal productivity, $f(x)$, which is the maximum that the incumbent firm would agree to pay him.

If $x' < x$, however, the worker remains at the incumbent firm, but his wage might be adjusted. In particular, if the expected value of remaining at the incumbent firm at wage $w$ is less than the outside option of moving to the poaching firm at the maximum wage $f(x')$, then the worker remains at the incumbent firm but renegotiates his wage using the outside option of the poaching firm. Otherwise, the worker remains at the incumbent firm and his wage remains unchanged.

### 4.2 Value Functions and Wage Functions

We restrict our analysis to steady-state equilibria. Let $V^u(a_i)$ denote the expected discounted value of an unemployed worker with ability $a_i$, and let $V^e(a_i, x, w)$ denote the expected discounted value of a worker with ability $a_i$ who is currently employed at a firm with match-specific productivity $x$ earning a wage $w$.

Since a firm generates zero output when unmatched, the expected surplus created by forming a match with productivity $x$ is $V_e(a_i, x, f(x)) - V^u(a_i)$, i.e., the worker’s value of being employed at a wage equal to the total output of the match, $f(x)$, less the worker’s value of being unemployed. Hence, it is straightforward to establish that an unemployed worker with ability $a_i$ will form a match with a new firm if, and only if, the match-specific productivity $x \geq x^*(a_i) \equiv x^*_i$, where $x^*_i$ satisfies

$$V^u(a_i) = V^e(a_i, x^*_i, f(x^*_i)), \quad i \in \{1, ..., N\}. \tag{1}$$

Following [Cahuc et al. (2006)](#), the worker will earn a wage $w^u(a_i, x)$ that satisfies

$$V^e(a_i, x, w^u(a_i, x)) = V^u(a_i) + \beta [V^e(a_i, x, f(x)) - V^u(a_i)]. \tag{2}$$

Intuitively, $w^u(a_i, x)$ yields the worker an expected utility equal to his outside option of unemployment plus a share $\beta$ of the match surplus.
Now consider an employed worker with ability \(a_i\), productivity \(x\), and wage \(w\) who contacts a new firm and draws match-specific productivity \(x'\). If \(x' > x\), the worker moves to the new firm at a wage \(w^e(a_i, x, x')\) satisfying

\[
V^e(a_i, x', w^e(a_i, x, x')) = V^e(a_i, x, f(x)) + \beta \left[V^e(a_i, x', f(x')) - V^e(a_i, x, f(x))\right].
\]  

(3)

Intuitively, \(w^e(a_i, x, x')\) yields the worker an expected utility equal to his outside option of remaining at the incumbent firm at the highest wage they are willing to pay, \(V^e(a_i, x, f(x))\), plus a share \(\beta\) of the surplus created by moving to the more productive match, \(V^e(a_i, x', f(x')) - V^e(a_i, x, f(x))\).

Alternatively, if \(x' \leq x\), the worker will remain at his current job, though he will use the threat of leaving to renegotiate his current wage if \(x\) is sufficiently high. In particular, let \(\bar{x}(a, x, w)\) denote the value of \(x'\) such that a currently employed worker of ability \(a\) with match-specific productivity \(x > x'\) would renegotiate her wage to exactly \(w\), i.e.,

\[
w = w^e(a_i, \bar{x}(a, x, w), x).
\]  

(4)

so that \(w^e(a_i, x', x) \leq w\) if \(x' \leq \bar{x}(a, x, w)\). Then the worker renegotiates her wage to \(w(a_i, x', x)\) if \(x' \geq \bar{x}(a_i, x, w)\), and otherwise her wage remains \(w\).

Using the thresholds described above, we can write the flow Bellman equation characterizing the value of unemployment for a worker with ability \(a_i\) as

\[
rV^u(a_i) = b + \sum_{j \in c} \lambda^u_j(a_i) \int_{x_i}^{x} [V^e(a_i, x, w^u(a_i, x)) - V^u(a_i)] dH_j(x|a_i).
\]

Since \(d\Gamma^u(x|a_i) = -\sum_{j \in c} \lambda^u_j(a_i) dH_j(x|a_i) < 0\), this expression simplifies to

\[
[r + \Gamma^u(x^*|a_i)] V^u(a_i) = b - \int_{x_i}^{x} V^e(a_i, x, w^u(a_i, x))d\Gamma^u(x|a_i).
\]  

(5)

In words, as in standard job search models, the value of unemployment is equal to the flow value of unemployment, \(b\), plus the option value of finding a job out of unemployment.

Following similar steps for employed workers reveals that

\[
[r + \delta + \Gamma^e(\bar{x}|a_i)] V^e(a_i, x, w) = w + \delta V^u(a_i) - \int_{\bar{x}}^{x} V^e(a_i, x, w^e(a_i, x', x))d\Gamma^e(x'|a_i)
\]

\[
- \int_{\bar{x}}^{x} V^e(a_i, x', w^e(a_i, x', x'))d\Gamma^e(x'|a_i),
\]  

(6)

where \(\bar{x} \equiv \bar{x}(a_i, x, w)\). Equation (6) illustrates that the expected utility of a currently employed worker takes into account the possibility of losing his job, the possibility of renegotiating his wage at
his current employer, and the possibility of moving to a new job.

4.3 Distribution of Workers

Unemployed workers of ability $a_i$ exit unemployment when they meet a firm and draw match-specific productivity $x \geq x^*_i$. Once employed, a worker moves only when it meets a new firm with a higher match-specific productivity. In this section, we use these transition rules to derive the distribution of workers across possible states.

To do so, let $\phi^u(a_i)$ denote the measure of unemployed workers with ability $a_i$, and let $\phi^e(a_i, x)$ denote the measure of workers with ability $a_i$ currently employed at a job with match-specific productivity $x$. It will be convenient to define the cumulative measure of employed workers with ability $a_i$ and match-specific productivity $x' \leq x$ by $\Phi^e(x|a_i) \equiv \int_{x'}^x \phi^e(a_i, x') dx'$. These equilibrium objects are characterized by three sets of conditions:

$$\pi_i = \phi^u(a_i) + \Phi^e(x_i^*|a_i)$$  \hspace{1cm} (7)

$$\dot{\phi}^u(a_i) = \delta \Phi^e(x_i^*|a_i) - \phi^u(a_i) \Gamma^u(x_i^*|a_i) = 0$$  \hspace{1cm} (8)

$$\dot{\Phi}^e(x|a_i) = -\Phi^e(x|a_i) [\delta + \Gamma^e(x|a_i)] + \phi^u(a_i) [\Gamma^u(x_i^*|a_i) - \Gamma^u(x|a_i)] = 0$$  \hspace{1cm} (9)

for all $i \in \{1, \ldots, N\}$ and $x \in [x_i^*, \overline{x}]$. Condition (7) simply requires that summing the measures of unemployed and employed workers with ability $a_i$ yields the (exogenously specified) aggregate measure of workers with ability $a_i$. Conditions (8) and (9) are steady-state conditions, equating the inflow and outflow of workers into every possible state.\footnote{We use the notation of, e.g., $\dot{\phi}^u(a_i)$ to denote the rate of change in the measure of unemployed workers of type $a_i$.}

For example, in equation (9), workers with ability $a_i$ and current productivity $x' \leq x$ exit when their match is destroyed, which occurs at rate $\delta$, or when they find a better match with productivity $x'' > x$, which occurs at rate $\Gamma^e(x|a_i)$. Meanwhile, unemployed workers with ability $a_i$ enter this state by meeting a firm and drawing productivity $x' \in [x_i^*, x]$, which occurs at rate $\Gamma^u(x_i^*|a_i) - \Gamma^u(x|a_i)$.

4.4 Equilibrium

A steady-state equilibrium is characterized by thresholds $x^*(a)$ and $\overline{x}(a, x, w)$, value functions $V^u(a)$ and $V^e(a, x, w)$, wage functions $w^u(a, x)$ and $w^e(a, x, x')$, and distribution functions $\phi^u(a)$ and $\Phi^e(x|a)$ satisfying equations (1)–(9).\footnote{Recall that, for ease of exposition, we denote $x^*(a_i)$ by $x_i^*$.} The following proposition provides a closed-form characterization of the equilibrium objects that are key to our analysis.\footnote{Given these expressions, the remaining equilibrium objects can be easily constructed.} The proof is in Appendix C.
Proposition 1. In a steady-state equilibrium, the wage functions are given by

\[ w^e(a_i, x, x') = f(x') - p(1 - \beta) \int_x^{x'} \frac{r + \delta + \Gamma^e(x''|a_i)}{r + \delta + \beta \Gamma^e(x''|a_i)} dx'', \tag{10} \]

for \( x' > x \geq x^*_i \), and

\[ w^u(a_i, x) = w^e(a_i, x^*_i, x), \tag{11} \]

for \( x \geq x^*_i \), where \( x^*_i \) satisfies

\[ f(x^*_i) = b + p\beta \int_{x^*_i}^x \frac{[\Gamma^u(x|a_i) - \Gamma^e(x|a_i)]}{r + \delta + \beta \Gamma^e(x|a_i)} dx \tag{12} \]

for \( i \in \{1, 2, ..., N\} \). The distribution functions are given by

\[ \phi^u(a_i) = \frac{\delta \pi_i}{\delta + \Gamma^u(x^*_i|a_i)} \text{ for all } i \in \{1, ..., N\}, \tag{13} \]

and

\[ \Phi^e(x|a_i) = \frac{\delta \pi_i [\Gamma^u(x^*_i|a_i) - \Gamma^u(x|a_i)]}{[\delta + \Gamma^u(x^*_i|a_i)] [\delta + \Gamma^e(x|a_i)]} \text{ for all } x \geq x^*_i \text{ and } i \in \{1, ..., N\}. \tag{14} \]

4.5 Key Model-Implicit Moments

We now illustrate how the framework developed above can be used to analyze and interpret the empirical regularities we documented in Section 3. As a first step, we derive the joint distribution of employed workers’ unobserved types, their match-specific productivities, and the channel through which they found their job. Then, we use this distribution to derive analytical expressions for several key model-implied moments, including the fraction of workers that used each job search channel, and the relationship between a worker’s job search channel, their wage, and their expected tenure. These expressions—which, to the best of our knowledge, are new to the literature—offer two important benefits when we calibrate the model in Section 5. First, they allow us to understand how the model’s structural parameters are identified from the target moments we choose. Second, they allow us to calibrate the model without resorting to costly simulations.

Joint Distribution of Type, Productivity, and Job Search Channel. Since workers’ future labor market transitions do not depend on the channel through which they formed their current match, the probability that a worker of type \( a_i \) currently employed with productivity \( x \) received her job through channel \( j \in \{B, F, O\} \) is

\[ \Lambda_j(a_i, x) = \frac{\phi^u(a_i)d\Gamma^u_j(x|a_i) + \Phi^e(x|a_i)d\Gamma^e_j(x|a_i)}{\sum_{j \in \{B, F, O\}} \phi^u(a_i)d\Gamma^u_j(x|a_i) + \Phi^e(x|a_i)d\Gamma^e_j(x|a_i)}. \]
To see why, note that the numerator represents the flow of (unemployed and employed) type $a_i$ workers into matches of quality $x$ through channel $j$, while the denominator represents the flow of type $a_i$ workers into matches of quality $x$ through any channel. Therefore, we can define the measure of workers of type $a_i$ currently employed with productivity $x$ that got their job through channel $j$ as

$$\phi_j^e(a_i, x) = \Lambda_j(a_i, x)\phi^e(a_i, x).$$ (15)

**Usage, Wages, and Tenure.** Integrating and summing $\phi_j^e(a_i, x)$ reveals that the fraction of currently employed workers who used channel $j$ to find their current job is

$$\frac{1}{1-u} \sum_i \int_{x_i^*}^{x} \phi_j^e(a_i, x) dx$$ (16)

where $u = \sum_i \phi^u(a_i)$ denotes the measure of unemployed workers.\(^23\)

To calculate average wages of workers who acquired their job through a specific job search channel, the following lemma is useful.\(^24\)

**Lemma 1.** For any wage $w \in [w^u(a_i, x), w^e(a_i, x, x)]$, the fraction of workers of type $a_i$ employed at a firm with productivity $x \geq x_i^*$ that earn a wage $w' \leq w$ is given by

$$G(w|a_i, x) = \frac{-\phi^u(a_i) d\Gamma^u(x|a_i) + \Phi^e(\bar{x}(a_i, x, w)|a_i) d\Gamma^e(x|a_i)}{\phi^e(a_i, x) [\delta + \Gamma^e(\bar{x}(a_i, x, w)|a_i)]}.$$ (17)

Since the distribution of wages across workers, conditional on $a_i$ and current productivity $x$, is the same for all $j \in \{B, F, O\}$, the average wage of currently employed workers who got their job through channel $j$ is thus

$$\frac{\sum_i \int_{x_i^*}^{x} \mathbb{E}[w|a_i, x] \phi_j^e(a_i, x) dx}{\sum_i \int_{x_i^*}^{x} \phi_j^e(a_i, x) dx},$$ (18)

where, letting $w \equiv w^u(a_i, x)$ and $\overline{w} \equiv w^e(a_i, x, x)$,

$$\mathbb{E}[w|a_i, x] = wG(w|a_i, x) + \int_{w}^{\overline{w}} wdG(w|a_i, x) = \overline{w}(a_i, x) - \int_{w}^{\overline{w}} G(w|a_i, x) dw.$$ (19)

---

\(^23\)Since the measure of workers is normalized to one, note that $u$ is also equal to the unemployment rate.

\(^24\)Note that we derive and target average wages instead of average starting wages. This is because, as is well known, the strategic wage protocol of Postel-Vinay and Robin (2002) and Cahuc et al. (2006) can often produce counterfactual starting wages for those workers hired out of unemployment. Indeed, if the option value of starting to climb the job ladder is sufficiently high, these models can even predict that workers accept negative wages early in their careers, which clearly violates constraints outside of the model (such as the minimum wage).

\(^25\)To see why, note that the current wage of a type $a_i$ worker with productivity $x$, $w^e(a_i, x', x)$, only depends on the value $x' < x$ of either his last job or his last offer (with $x' = x^*$ if he was last unemployed). Given the nature of Poisson arrivals, $x'$ does not depend on the channel through which the worker got his current job.
Similarly, since the expected tenure of a worker of type $a_i$ who is currently employed at a firm with productivity $x$,

$$
\tau(x, a_i) = \frac{1}{\delta + \Gamma^e(x|a_i)},
$$

is also independent of the channel through which the worker got the job, the expected tenure of currently employed workers who got their job through channel $j$ is equal to

$$
\sum_i \int_{x^*} \tau(x, a_i) \phi^e_j(a_i, x) \, dx 
\sum_i \int_{x^*} \phi^e_j(a_i, x) \, dx.
$$

(20)

5 Quantitative Exercise

In this section, we calibrate the model to key moments in our data. This exercise generates new qualitative insights into the role of referrals in the labor market, along with new quantitative insights into how much they contribute to employment, earnings, inequality, and output. Importantly, for both sets of insights, we find that the distinction between referrals from business contacts and those from family and friends is crucial.

Qualitative insights. Interpreting the data through the lens of our model reveals the underlying relationships between the job search channels that workers use, their unobserved types, and their subsequent labor market outcomes. These relationships, in turn, are informative about what referrals actually do, i.e., which theories of referrals are consistent with the patterns we observe among workers who use these distinct job search channels.

We find that a key source of dispersion in employment and earnings derives from heterogeneity in both the rate at which workers meet firms and the productivity of these potential matches. Moreover, this heterogeneity across worker types largely manifests itself through differences in the frequency with which workers utilize referrals from business contacts (and, to a lesser extent, other formal channels). Referrals from family and friends, in contrast, are used more uniformly across worker types, and generate relatively high productivity matches, on average, conditional on worker type.

Hence, referrals from business contacts appear to effectively screen workers based on their unobservable, \textit{ex ante} type, as in theories à la Montgomery (1991) which ascribe a central role to a referral’s ability to overcome problems associated with asymmetric information. Alternatively, since referrals from family and friends tend to generate good matches independently of a worker’s underlying type, these types of referrals are most consistent with theories in which a referral improves match quality \textit{ex post}, perhaps by reducing symmetric uncertainty or inefficiencies that derive from moral hazard.
Quantitative insights. The calibrated model also allows us to quantify the effect of these two types of referrals on labor market outcomes across workers and occupations. We find that referrals from family and friends are a crucial job search channel for low ability workers, particularly in low skill occupations, as these workers struggle to meet firms through other channels. For example, in low skill labor markets, we estimate that referrals from family and friends account for about 16% of earnings for low ability workers. Referrals from business contacts, in contrast, are used more frequently by high ability workers, and their contribution to earnings is more pronounced in high skill occupations.

Our quantitative results also offer new a perspective on certain normative questions regarding the use of referrals. For example, an important open question in the literature is whether referrals mitigate or exacerbate earnings inequality. Our answer, again, is that it depends on the type of referral. On the one hand, since referrals from family and friends tend to increase the wages of workers with otherwise dim employment prospects, we find that eliminating these referrals (say, through nepotism laws) would decrease output and increase inequality. On the other hand, since referrals from business contacts primarily increase the wages of relatively high-earning workers, shutting down this channel introduces a genuine trade-off, reducing inequality at the cost of lower output.

5.1 Calibration: Maintained Assumptions

We calibrate the model at a monthly frequency. Since our empirical results highlight the differential role of referrals across high- and low-skill jobs, we split our data into two sub-samples: those workers with a bachelors degree or more (whom we refer to as “high skill”), and those with some college or less (whom we refer to as “low skill”). We think of the two markets as distinct labor markets, and hence calibrate the model separately for each skill group.

In both markets, the discount factor, $r$, is chosen to yield an annual discount rate equal to 95%. We also assume, in both markets, that there are two types of unobserved ability $a_i$, and normalize $a_1 = 1$ and $a_2 = 2$. Finally, we choose functional forms for the production and matching technologies. In particular, we assume that the production technology is linear, $f(x) = px + c$, while the matching technologies are given by $\Gamma_u^j(x|a) = \lambda_u^j(a) [1 - H_j(x|a)]$ and $\Gamma_e^j(a) = \theta \Gamma_u^j(a)$ for $j \in \{B, F, O\}$, so that $\theta$ represents the relative efficiency of searching on the job.

We assume that the rate at which workers of ability $a_i$ meet firms through channel $j$ satisfies $\lambda_u^j(a) = \alpha_j a + \kappa_j$, while the distribution of match-specific productivity, $H_j(x|a_i)$, is defined by a beta distribution with shape parameters $\xi_j a$ and $\eta$. The parameter $\alpha_j$ captures the effect of a worker’s ability on the rate at which she meets firms through channel $j$, while $\kappa_j$ captures level differences in meeting rates across channels—allowing, e.g., meetings through formal (or “other”) channels to

26 As we explain below, we choose to distinguish these two markets by education, as opposed to the NPB score of the occupation, to leverage existing estimates of a key parameter of this model across education groups.

27 We also experimented with versions of the model with more than two types, but our calibration results loaded most of the weight on just two types.
occur more frequently for workers of all abilities. The parameters $\xi_j$ and $\eta$ jointly determine the mean and variance of the distribution of match-specific productivity draws through channel $j \in \{B, F, O\}$, along with the sensitivity of these moments to workers’ ability $a_i$.

5.2 Parameters and Targets in High- and Low-Skill Markets

In each market (low and high skill), we set the value of the bargaining power parameter, $\beta$, using an estimate from outside of our sample. In particular, within the context of a model also based on Cahuc et al. (2006), Lise et al. (2016) use data from the NLSY to estimate $\beta$ across education groups. We use their estimates of $\beta = 0.188$ and $\beta = 0.272$ for the low and high skill markets, respectively.

Sixteen parameters remain for each market: $\{\alpha_j, \kappa_j, \xi_j\}_{j \in \{B, F, O\}}$ and $\{\eta, \theta\}$ determine the arrival rate and quality of matches through the three different channels; $\delta$ determines the rate of job destruction; $\{p, c\}$ determine the production technology; $b$ determines the flow value of unemployment; and $\pi_1$, the proportion of workers of ability $a_1$, determines the distribution of unobserved heterogeneity (ability). We calibrate these parameters to match sixteen moments in our data. To do so, we calculate a vector of moments from the data, $\hat{m}$, and then derive the counterparts of these moments (using our analytical results) in the model, $\tilde{m}(\chi)$, for a particular vector of parameter values, $\chi$. The calibration procedure then iterates over $\chi$ to minimize the loss function

$$L(\chi) = -\frac{1}{2} (\hat{m} - \tilde{m}(\chi))^T \hat{W}^{-1} (\hat{m} - \tilde{m}(\chi)),$$

where $\hat{W}$ is the diagonal of the covariance matrix of $\hat{m}$, which is estimated via the nonparametric bootstrap. Appendix D contains a more detailed description of both the empirical targets and the model counterparts.

The first three moments are relatively standard: for each skill group, we target the aggregate unemployment rate, the job destruction (EU) rate, and the job-to-job (EE) transition rate from our sample. Leveraging the detailed description of workers’ job search experiences in the SCE, the fourth and fifth moments we target are the rate at which employed and unemployed workers contact (but do not necessarily match with) firms each month. The sixth and seventh moments speak to residual wage dispersion. We first calculate the distribution of wages in each subsample (high and low skill markets) after controlling for observable characteristics. Then, we calculate the fraction of workers in the model earning less than the wages that lie at the 25th and 75th percentiles of the empirical distribution. The targets, of course, are 0.25 and 0.75, respectively.

The nine remaining moments are specific to the relationship between job search channels and labor

---

28Formally, given our parameterization, the mean of each distribution is $\frac{\xi_j a}{\xi_j a + \eta}$ and the variance is $\frac{\xi_j a \eta}{(\xi_j a + \eta)^2 (1 + \xi_j a + \eta)}$.

29Specifically, we use the same set of variables used in the regressions in Section 3: individual controls, time and region fixed effects, and the NPB score.
market outcomes. To start, using the expression derived in (16), we target the fraction of all employed workers that used a business referral \((j = B)\) to find their current job, and the fraction that used a referral from family or friends \((j = F)\). Second, using the expression derived in (18), we target the average wage of currently employed workers who got their job through channel \(j \in \{B, F, O\}\). For the next two moments, we use the expression derived in (20) to target the average tenure of workers who got their job through channel \(j \in \{B, F\}\), relative to the average tenure of the non-referred. \(^{30}\)

Finally, a key mechanism in our model implies a connection between the channel that a worker uses to find their job and their place in the wage distribution: as we discuss in greater detail below, type \(a_2\) workers earn higher wages and are more likely to use channel \(B\), while type \(a_1\) workers earn lower wages and are more likely to use channel \(F\). Hence, following the logic in Arbex et al. (2019), we target two additional moments that capture how the fractions of employed workers who used channels \(B\) and \(F\) change with wages. In particular, for \(j \in \{B, F\}\), we target the difference in the fraction of workers in the top wage quartile that used channel \(j\) to find their job and the fraction of workers in the bottom wage quartile that used channel \(j\) to find their job.

Table 6 reports the model fit for each of the two sub-samples. As one can see, the model is able to match the data remarkably well. Table 12 in Appendix D reports the parameter values that emerge from the calibration.

5.3 Qualitative Insights from Calibration

Our calibration reveals the properties of the matching and production technologies—i.e., the relationships between workers’ unobserved types, the frequency with which they contact firms through different channels, and the output generated by these potential matches—that are necessary to generate the empirical patterns we observe in the data. In this section, we highlight the main qualitative properties of these technologies (implied by the calibrated parameter values), explain how these properties enable the model to match the target moments in the data, and discuss the relationship between these properties and existing theories of referrals.

**Key properties of calibrated model.** Given the large number of parameters in our model, and the myriad ways they interact with one another in equilibrium, it is difficult to interpret many of the parameter values directly. Instead, Table 7 reports a few summary statistics that reveal several key properties of the calibrated model environment.

The first key insight is that matching the data through the lens of our model requires significant heterogeneity in the rate at which otherwise similar workers receive offers (through any channel), both

\(^{30}\)As noted earlier in the text, in our data we observe tenure *up to the sampling date*, and not the total tenure of a completed employment spell. Taking this into account, we only target the difference in observed tenures across job search channels here, and not the levels. Later, when we simulate the model, we compare the two objects—total tenure, and tenure up to a sampling date—using model-generated data to check that they are similar. We find that they are.

Notes: This table reports the values of our 16 targeted moments in the data and as computed analytically in our model, separately for the high skill and low skill markets.

when they are unemployed and when they are employed.\(^{31}\) For example, in both the high and low skill markets, the overall rate at which unemployed workers of type \(a_2\) match with firms, \(\Gamma^u(x^\star_2|a_2)\), is approximately six times larger than the matching rate of type \(a_1\) unemployed workers.\(^{32}\)

The second key insight is that this heterogeneity stems mostly from differences in the arrival rate of offers through business referrals and, to a lesser extent, other (formal) channels. For example, in the low skill market, the rate at which type \(a_2\) unemployed workers match with firms through a business referral, \(\Gamma^u_B(x^\star_2|a_2)\), is approximately forty times larger than the corresponding matching rate of type \(a_1\) unemployed workers. Offers that arrive through referrals from family and friends, in contrast, are much less sensitive to a worker’s unobserved type.

The third key insight is that there are important differences in expected output across channels. In both markets, \(F\) referrals create the best matches, conditional on worker type. For example, in the high skill market, the expected output for a type \(a_2\) worker from a match generated by a \(F\) referral is 45.18 (measured in hourly output), which is 27% and 15% higher than the expected output from a match via the \(B\) and \(O\) channels, respectively. However, since \(B\) referrals are used much more extensively by type \(a_2\) workers, they are associated with higher productivity matches overall. In other words, while \(B\) referrals lead to higher productivity matches unconditionally, \(F\) referrals generate

\(^{31}\)In a related paper, [Gregory et al. (2021)] also find that unobserved heterogeneity in the frequency of employment transitions is an important factor in understanding labor market outcomes.

\(^{32}\)Recall that the arrival rate of offers for employed workers are simply scaled by \(\theta\), so that the statements above regarding arrival rates apply equally well to employed and unemployed workers.
higher productivity matches conditional on ability.

Finally, while we observe similar qualitative patterns in both high and low skill markets, there are (at least) two important quantitative differences. First, while high ability workers are more likely to use $B$ relative to $F$ in both markets, the difference is more pronounced in the high skill market. For example, comparing $\Gamma_B^u(x^*_2|a_2)$ to $\Gamma_F^u(x^*_2|a_2)$, an unemployed worker of type $a_2$ is more than ten times as likely to find a job through $B$ than $F$ in the high skill market, but only three times more likely to do so in the low skill market. Second, the difference in expected output of workers with different abilities is also more pronounced in the high skill market; on average, type $a_2$ workers generate nearly twice as much output in a match (across all channels) in the high skill market, but are only modestly more productive in the low skill market. This difference is partly due to better match quality (higher average $x$) for type $a_2$ workers, and also due to the fact that our calibration implies that output for high skill occupations is more sensitive to match quality. In particular, the calibrated value of $p$ in the production function $f(x) = px + c$ is more than twice as large in the high skill market than the low skill market.

Notes: This table reports several summary statistics using the calibrated parameter values. The matching rate is the probability of receiving an offer greater than or equal to the reservation value of the match-specific productivity. Expected output is measured as expected hourly output.

How do these properties generate the patterns we observe in the data? The matching rates in Table 7 are helpful for understanding how the model generates the differential usage rates of channels $B$ and $F$, within and across markets. For example, in the high skill market, meetings occur relatively frequently through $B$, compared to the overall meeting rate, whereas meetings through $B$ are a smaller proportion of meetings in the low skill market. The opposite is true for channel $F$: these types of meetings constitute a larger share of overall meetings in the low skill market, relative to the high skill market.

To understand how the model generates average wages and tenure conditional on job search channel, note that the difference in the arrival rate of meetings through channel $B$ across abilities is much more pronounced than the difference in the arrival rate of meetings in channel $F$, i.e.,
\( \Gamma_B(\cdot|a_2)/\Gamma_B(\cdot|a_1) > \Gamma_F(\cdot|a_2)/\Gamma_F(\cdot|a_1) \). As a result, a randomly selected employed worker who got her job through channel \( B \) is more likely to be type of \( a_2 \), while a worker who got his job through channel \( F \) is more likely to be of type \( a_1 \). Moreover, ceteris paribus, the expected output of a type \( a_2 \) worker is larger than that of a type \( a_1 \) worker and, after forming a match, type \( a_2 \) workers receive offers more frequently than type \( a_1 \) workers. Taken together, these properties imply that a randomly selected worker who got her current job through channel \( B \) will have a relatively high wage but a relatively short tenure, whereas a randomly selected worker who got his current job through channel \( F \) will have a lower wage but stay at the firm for a longer tenure.

**How do these properties relate to existing theories of referrals?** The empirical analysis in Section 3 revealed that distinguishing between different types of referrals is crucial for uncovering certain patterns in the data: workers who used business referrals to find their current job experienced significantly different—and, in fact, opposite—labor market outcomes, relative to workers who used a referral from a family or friend. However, the data alone do not explain how or why these two job search methods exhibit different correlations with a worker’s wage or propensity to switch jobs, or why these correlations vary systematically across occupations with different skill requirements. In this section, we exploit the results from our calibration exercise to show how interpreting the data through the lens of a structural model can help us understand the distinct roles that referrals from business contacts and family/friends play in the match formation process.

On the one hand, as we discussed above, a worker’s tendency to meet a firm through a business referral is highly sensitive to the worker’s *ex ante* type, \( a_i \). As a result, business referrals frequently initiate contact for type \( a_2 \) workers who are likely to have high match-specific productivity at a firm, and are rarely used to initiate contact for type \( a_1 \) workers who are typically less productive. Hence, business referrals appear most consistent with theories based on a referrer’s ability to overcome *adverse selection* by screening workers based on their expected productivity at the firm, as conjectured by [Montgomery (1991)] and others.

On the other hand, referrals from family and friends appear to generate relatively high productivity matches independently of a worker’s underlying type. This property is consistent with theories that ascribe a central role to the ability of referrals to generate good matches *ex post*. One such theory, put forward by [Simon and Warner (1992)], among others, postulates that referrals improve workers’ and firms’ ability to overcome *symmetric uncertainty* by learning about their match-specific productivity more efficiently. An alternative theory, which is also consistent with the properties of \( \Gamma_F(\cdot) \) revealed by our calibration exercise, is that referrals from family and friends help overcome *moral hazard*. According to this theory (put forward by, e.g., [Heath (2018)]), a worker referred by a family or friend has more incentive to work hard and less incentive to shirk.

The finding that low types \( (a_1) \) rely much more heavily on referrals from friends and family is consistent with the idea that referrals can act as a “last resort” for individuals with few outside options,
as espoused by [Loury] (2006). However, note that our findings are not consistent with theories of referrals based on nepotism or other forms of favoritism, in which referred workers are, on average, less productive than workers hired through more formal channels (see, e.g., [Bandiera et al.] 2009; Fafchamps and Moradi 2015).

5.4 Quantitative Insights from Calibration

In the previous section, we used the calibrated model to explore the qualitative properties of the matching technologies across job search channel, worker ability, and occupational skill requirement, which revealed a number of new insights about the role of referrals from business contacts and family/friends in the match formation process. In this section, we use the calibrated model to explore the quantitative effects of referrals from business contacts and family and friends on employment, earnings, output, and inequality.

To do so, we simulate the labor market experience of a cohort of workers who enter the market unemployed at $t = 0$, assuming they have access to all three job search channels, and follow them for a period of ten years. Then, we repeat the simulation but shut down referrals from business contacts—i.e., we set $\Gamma_B(x|a) = 0$—and evaluate the labor market outcomes of different types of workers ($a_1$ and $a_2$) across low- and high-skill labor markets. Finally, we repeat the exercise but shut down referrals from family and friends, while restoring a worker’s ability to meet firms through business contacts.

The contribution of referrals to earnings. Table 8 reports the average annual earnings, the average employment rate, and the average wage (conditional on being employed) of workers during their first ten years in the labor market. Several interesting insights emerge from the table.

First, and perhaps most striking, is the extent to which low ability workers depend on referrals from family and friends. For instance, our simulations suggest that approximately 16% (7%) of earnings of low ability workers in low (high) skill occupations can be attributed to referrals from family and friends. Intuitively, referrals from family and friends are critically important to this subset of workers for two reasons: first, because they struggle to contact firms through other channels ($O$ or $B$); and second, because matches formed through family and friends tend to be high quality matches (for all abilities).

33 The results reported below are similar at 20 and 30 year horizons, as well.

34 Note that, in these quantitative exercises, we assume that shutting down one channel has no effect on the arrival rate or quality of matches generated by other channels. This allows for a clean decomposition of the relative contribution of each channel to labor market outcomes. Moreover, existing evidence shows that workers already exploit available job search channels, with plenty of time to spare; see, e.g., [Mukoyama et al.] (2018). This suggests that workers without access to one particular job search channel may not be able to easily increase the arrival rate and/or quality of matches through an alternative channel.

35 Note that the average employment rate reported in Table 8 is lower than in the steady state because, in the simulation, each individual starts off unemployed.

Notes: This table reports estimates from a simulation of our calibrated model in which a cohort of 30,000 workers enters the market unemployed. We follow this cohort for a period of 10 years. The top panel reports average annual earnings over these 10 years in both markets (high and low skill) for low and high ability workers ($a_1$ and $a_2$, respectively). The middle panel reports the average employment rates for each of these groups, and the bottom panel reports average hourly wages of employed workers. In each panel, the top row reports results from our benchmark model, while the second and third rows, respectively, report how the baseline results change when we shut down referrals from business contacts and family/friends.

Second, while our calibration suggests that low ability workers depend heavily on referrals from family and friends, high ability workers do not: in both low and high skill markets, high ability workers match with firms through channels $B$ and $O$ sufficiently frequently that shutting down channel $F$ has very modest effects on earnings and, in fact, no effect on employment. Interestingly, while the contribution of referrals from family and friends is very different across workers’ abilities, it is roughly even across low and high skill markets, accounting for about 5% of total earnings in each.

The effects of referrals from business contacts are quite different: while the contribution of channel $B$ to labor market outcomes is more even across workers’ abilities, our calibration suggests that workers’ networks of business contacts are considerably more important in high skill occupations than in low skill occupations. For example, shutting down channel $B$ reduces earnings by about 6% in the former, and about 3% in the latter. Intuitively, there are several reasons why the effects of business referrals are more pronounced in high skill occupations. For one, referrals from business contacts are used more frequently in the high skill market, especially among high ability workers who have higher average match-specific productivity. Moreover, since the calibrated production function is steeper in the high skill market, a reduction in average match quality translates into a larger loss in output.

In general, shutting down any channel $j \in \{B, F, O\}$ has three effects: workers spend more time in unemployment; they have lower match-specific productivity, on average, when matched; and they receive a smaller share of the surplus, since outside offers arrive more slowly. We find that, for both $a_1$ and $a_2$, about two-thirds of the loss in earnings from shutting down channel $B$ stems from employed workers earning lower wages—both because they have lower match-specific productivity and because they get fewer outside offers—while about one-third of the decline stems from lower employment rates. However, whereas the loss in earnings from shutting down $F$ is almost entirely due to the wage effect for high ability workers, it is split approximately evenly between wage and employment effects for low ability workers.

36
Finally, since the quantitative effect of referrals differs significantly both across $B$ and $F$, and across low and high skill occupations, Table 8 illustrates again the importance of distinguishing between different types of referrals and the different types of occupations in which they are used. Importantly, these results also highlight the advantage of interpreting the data through the lens of a model. For instance, the regression results in Table 3, which report the correlation between the use of these two types of referrals and wages, might lead one to believe that referrals from business networks have a large, positive effect on workers’ wages, while referrals from family and friends have modest, negative effects on wages. However, by allowing for unobserved heterogeneity and accounting for selection effects, our modeling exercise illustrates that this conclusion would be erroneous. Instead, our calibration reveals that referrals from family and friends have a large, positive effect on workers’ wages, but they tend to be used by workers who otherwise struggle to find jobs (and hence earn, on average, lower wages).

**Referrals, output, and inequality.** While referrals are widely regarded as an important channel for matching workers and firms, a central, yet open question is whether referrals mitigate or exacerbate earnings inequality. More specifically, do referrals primarily help workers with dim employment prospects to find good-paying jobs? Or, instead, do they mostly help relatively well-connected, high-wage workers to earn even more? The answers to these questions are key for assessing the welfare implications of referrals and evaluating an explicit role for referrals in the context of labor market policies.

In Table 9, we report the change in total output and inequality—as measured by the standard deviation of earnings—in the simulations described above, in which we separately shut down $B$ and $F$ in low and high skill labor markets. The table reveals that the relationship between referrals and inequality again relies on the crucial distinction between referrals from different sources.

In particular, the simulations reveal that referrals from business contacts increase earnings inequality, particularly in high skill occupations, as they primarily serve to increase wages of high ability, well-paid workers (and offer little assistance to low ability, low-paid workers). Referrals from family and friends, however, do the exact opposite: they reduce earnings inequality, particularly in low skill occupations, by increasing employment and wages among low ability workers (while doing very little for high ability, high-wage workers).

Hence, the central question of whether referrals generate a trade-off between output and inequality depends crucially on the distinction between these two types of referrals. In general, employers almost always allow—and, indeed, encourage—their employees to refer candidates from their business or social network. However, out of concerns for nepotism, some employers do not allow current employees to refer their relatives. Interestingly, our results suggest that these types of restrictions may actually generate less output and greater inequality, as they do the most damage to workers who struggle to find work through other channels.

Notes: This table reports estimates from a simulation of our calibrated model in which a cohort of 30,000 workers enters the market unemployed. We follow this cohort for a period of 10 years. The left panel measures average (hourly) output over these 10 years, and the right panel measures the standard deviation in earnings across workers. In the first row we report these measures separately by market and by ability type. In the second and third rows we report how these baseline results change when we shut down business and family/friends referrals in the model.

6 Concluding Remarks

A longstanding challenge in labor economics is understanding the channels through which workers and firms form productive matches, and the implications for labor market outcomes. In surveys of both workers and firms, referrals are often cited as a key input into the match formation process. However, while there may be a consensus that referrals are widely used, there is far less agreement about who uses them most frequently, why they are valuable, or how they ultimately affect match quality, wages, turnover, inequality, and output.

In this paper, we try to make progress on these important questions. Our contribution can be broken down into three parts. First, leveraging a relatively new dataset, we show that clear patterns emerge from the data only after distinguishing between different types of referrals and different types of jobs. Second, by interpreting these patterns through the lens of a model, we are able to assess various theories of referrals and explore which mechanisms are (or are not) consistent with the patterns we find in the data. Lastly, by further exploiting our calibration results, we are able to derive quantitative estimates of the contribution of referrals from different sources in low- and high-skill labor markets.

We find that referrals from friends and family are a crucial source of jobs for a certain subset of workers that struggle to generate offers and matches through more traditional channels. Indeed, this type of referrals improves earnings and employment outcomes, and represents an important force for reducing earnings inequality. In contrast, business referrals tend to increase the wages of workers who have relatively good employment prospects to begin with. Hence, the use of business referrals, which is typically encouraged by firms, increases output but also exacerbates earnings inequality. These findings are important in assessing the welfare implications of referrals and in evaluating their role within the broader context of labor market policies.

While this paper focuses on the direct effects of referrals on labor market outcomes, we believe our
results could deepen our understanding of other economic phenomena as well. As a leading example, consider the literature that studies worker mobility across geographic locations. Within this literature, one key finding is that substantial moving costs are needed to rationalize the internal migration patterns observed in the data, particularly for low-skill workers (Kennan and Walker, 2011; Diamond, 2016; Piyapromdee, 2021). In addition, the literature studying the Moving to Opportunity programs has found that, despite previous research documenting the importance of neighborhoods for economic outcomes, moving families from high-poverty to low-poverty neighborhoods has no significant effect on earnings or employment (Katz et al., 2001; Chetty et al., 2016). Since we show that low-skill workers rely heavily on referrals from friends and relatives, and relocating often severs a worker’s connections to many contacts in their social network, our results provide a natural explanation for—and a bridge between—these two important findings. Thus, by offering a deeper explanation of the sources of migration costs, our findings have potentially important implications for the design of social programs aimed at improving labor market outcomes by promoting migration. Analogously, our results on referrals from business contacts could provide new insights into the costs associated with occupational mobility, as changing occupations may significantly alter the structure of one’s business network. We leave exploring and deepening these connections for future work.
A Data Description

In this appendix we describe how we arrive at our final estimation sample and provide additional details regarding the construction of our wage and tenure variables.

Our data set combines the annual Job Search Surveys of the SCE from 2013-2018. We keep individuals that are of working age (18 to 64) and that are not self-employed, for a total of 5,099 observations. After excluding individuals who work in military occupations and dropping a small number of observations with missing demographic data or inconsistent wage data, we are left with a final sample of 5,062 observations.

All three wage measures (current, starting, previous) are reported as either hourly, weekly, or annual. Survey respondents are also asked to report their usual hours spent at their job per week for both their current job and their previous job.\footnote{For the 2013 data, survey respondents were not directly asked the usual hours on their previous job, and instead were asked how much their hours increased or decreased from their previous job. We use this change and the reported usual hours at the current job to construct previous hours.} We divide weekly wages by usual hours and annual wages by usual hours and by 52 to convert everything to hourly wages. We then deflate all three nominal wage measures using the relevant CPI index obtained from the BLS.

For job tenure, the SCE survey asks workers the month and year in which they started their current job. We use this information to compute the duration of the worker’s current job at the time of the survey.
Additional Empirical Results

Job Satisfaction and Referrals

Table 10 reports results from linear regressions relating the job search method used to find a worker’s current job and their reported satisfaction with that job in response to the following questions:

1. “Taking everything into consideration, how satisfied would you say you are, overall, in your current job?”
2. “How satisfied would you say you are with your level of compensation at your current job?”
3. “How satisfied would you say you are with other aspects of the job, such as benefits, maternity/paternity leaves, flexibility in work hours, etc?”
4. “How well do you think this job fits your experience and skills?”
5. “How would you rate the opportunities for a promotion or other career progression with your current employer, over the next three years?”

For the first three measures respondents are asked to respond on a scale from 1-5 capturing “very dissatisfied” to “very satisfied”. For the last two, they are asked to respond on a scale from 1-7 ranging from “very poor” to “very good”. As the results indicate, there are no systematic differences in job satisfaction across job search method.

</table>

Notes: Estimates are from regressions regarding five different measures of job satisfaction. Individual controls include age, gender, race, marital status, number of children under the age of 6, and home ownership status. Standard errors are presented in parentheses below the point estimates. *** denotes significance at the 1% level, ** denotes significance at the 5% level, and * denotes significance at the 10% level. These questions were not asked in 2013, which reduces the number of observations by 711. For 3 of the measures we do not observe satisfaction for 1 individual.
Search Behavior of Employed Workers and Referrals

Table 11 reports results from regressions relating four measures of on-the-job search to the method used to find a worker’s current job. The measures we use are number of job applications sent out in the past 4 weeks, whether any job search was performed over the past weeks as well as the past 12 months, and the number of hours of job search over the past 4 weeks. Overall there do not seem to be any large differences in on-the-job search based across job finding method. There is some weak evidence that individuals who found their job via family/friends referral are slightly less likely to have searched over the past 12 months, although not over the past 4 weeks. There is also some weak evidence that business referred workers search more in terms of hours, but not in terms of overall probability.

<table>

</tr>
<tr>
<td>N</td>
</tr>
</tbody>
</table>

Notes: Estimates are from regressions on the total number of applications sent in the past 4 weeks, indicators for whether individuals have searched at all for a job over the past 4 weeks and past 12 months, and the total number of job search hours over the past 4 weeks. Individual controls include age, gender, race, marital status, number of children under the age of 6, and home ownership status. Standard errors are presented in parentheses below the point estimates. ** denotes significance at the 1% level, * denotes significance at the 5% level, and * denotes significance at the 10% level. There are 14 observations for which we do not observe search behavior over the past 4 weeks. For search behavior over the past 12 months we exclude observations for which individuals have a tenure of less than 12 months, since we cannot determine whether they were searching on or off the job.
C  Omitted Proofs

Proof of Proposition 1

First, note that, by construction, the \( \hat{x}(a, x, f(x)) \) threshold has the following properties, which are useful later:

\[
x = \hat{x}(a, x, f(x)) \tag{21}
\]
\[
V^e(a_i, x, w) = V^e(a_i, \hat{x}(a_i, x, w), f(\hat{x}(a, x, w))) \tag{22}
\]

Now, by substituting (10), equation (6) can be written

\[
[r + \delta + \Gamma^e(\hat{x})]V^e(a_i, x, w) = w + \delta V^u(a_i) + V^e(a_i, x, f(x)) [\beta [\Gamma^e(\hat{x}) - \Gamma^e(x|a_i)] + (1 - \beta)\Gamma^e(x|a_i)]
\]

\[
- (1 - \beta) \int_x^{\hat{x}} V^e(a_i, x', f(x'))d\Gamma^e(x'|a_i) - \beta \int_{\hat{x}}^{\infty} V^e(a_i, x', f(x'))d\Gamma^e(x'|a_i),
\]

where, again, we have used \( \hat{x} \equiv \hat{x}(a_i, x, w) \) to economize on notation.

Setting the wage \( w = f(x) \), substituting (21), and simplifying yields

\[
[r + \delta + \beta \Gamma^e(x)]V^e(a_i, x, f(x)) = f(x) + \delta V^u(a_i) - \beta \int_x^{\infty} V^e(a_i, x', f(x'))d\Gamma^e(x'|a_i).
\]

Differentiating with respect to \( x \) then yields

\[
\frac{\partial V^e(a_i, x, f(x))}{\partial x} = \frac{p}{r + \delta + \beta \Gamma^e(x|a_i)}. \tag{23}
\]

Using this relationship in the expression for \( V^e(a_i, x, w) \) above, integrating by parts, using (6), and simplifying yields

\[
(r + \delta)V^e(a_i, x, w) = w + \delta V^u(a_i)
\]

\[
+ p \left[ (1 - \beta) \int_x^{\hat{x}} \frac{\Gamma^e(x'|a_i)}{r + \delta + \beta \Gamma^e(x'|a_i)}dx' + \beta \int_{\hat{x}}^{\infty} \frac{\Gamma^e(x'|a_i)}{r + \delta + \beta \Gamma^e(x'|a_i)}dx' \right]. \tag{24}
\]

Plugging in \( w = w^e(a_i, x, x') \), subtracting \( (r + \delta)V^e(a_i, x, f(x)) \), and using (6) yields

\[
(r + \delta) [V^e(a_i, x', f(x')) - V^e(a_i, x, f(x))]
\]

\[
= w^e(a_i, x, x') - f(x) + p \left[ (1 - \beta) \int_x^{x'} \frac{\Gamma^e(x''|a_i)}{r + \delta + \beta \Gamma^e(x''|a_i)}dx'' - \beta \int_{x'}^{\infty} \frac{\Gamma^e(x''|a_i)}{r + \delta + \beta \Gamma^e(x''|a_i)}dx'' \right].
\]
\( \hat{x}(a_i, x, w^e(a_i, x, x')) = x \). Using (23) yields

\[
\begin{align*}
 w^e(a_i, x, x') &= \frac{p}{r + \delta + \beta \Gamma^e(x'|a_i)} \Gamma^e(x'|a_i) dx' + f(x) - p(1 - 2\beta) \int_x^{x'} \frac{\Gamma^e(x''|a_i)}{r + \delta + \beta \Gamma^e(x''|a_i)} dx'.
\end{align*}
\]

Straightforward algebra then yields the expression in (10).

Next, to characterize \( x_i^* \), note that we can use (2) and (23) to get that

\[
\begin{align*}
 rV^u(a_i) &= b - \int_{x_i^*}^{x} [V^e(a_i, x, w^u(a_i, x)) - V^u(a_i)] d\Gamma^u(x|a_i) \\
 &= b - \beta \int_{x_i^*}^{x} [V^e(a_i, x, f(x)) - V^u(a_i)] d\Gamma^u(x|a_i) \\
 &= b + \beta \int_{x_i^*}^{x} \frac{p\Gamma^u(x|a_i)}{r + \delta + \Gamma^e(x|a_i)} dx, \quad (25)
\end{align*}
\]

where the last equality follows from integration by parts. We can also use (1) and (24) to write

\[
\begin{align*}
 rV^e(a_i, x_i^*, f(x_i^*)) &= f(x_i^*) + \delta V^u(a_i) + \beta \int_{x_i^*}^{x} \frac{p\Gamma^e(x|a_i)}{r + \delta + \Gamma^e(x|a_i)} dx \\
 \Rightarrow rV^u(a_i) &= f(x_i^*) + \beta \int_{x_i^*}^{x} \frac{p\Gamma^e(x|a_i)}{r + \delta + \Gamma^e(x|a_i)} dx. \quad (26)
\end{align*}
\]

Equating (25) and (26) yields (12).

Finally, to characterize the equilibrium distributions, note that substituting (7) into (8) yields (13), and substituting (13) into (9) then yields (14).

**Proof of Lemma 1**

Let \( G(w|a_i, x) \) denote the fraction of type \( a_i \) workers currently employed at a firm with productivity \( x \) that earn a wage \( w' \leq w \). In a steady-state equilibrium, the outflow of such workers is

\[
G(w|a_i, x)\phi^e(a_i, x) \left[ \delta + \Gamma^e (\hat{x}(a_i, x, w)|a_i) \right]. \quad (27)
\]

Intuitively, the product of the first two terms yields the measure of workers of type \( a_i \) employed at a firm with productivity \( x \) that earn a wage \( w' \leq w \). The third term yields the rate at which these workers exit the set, either because the job is destroyed or because they contact a new firm with productivity \( x' > \hat{x}(a_i, x, w) \).
The inflow of workers into this set can be written

$$
\phi^u(a_i) \sum_j \lambda_j^e(a_i) h_j(x|a_i) + \Phi^e(\widehat{x}(a_i, x, w)|a_i) \sum_j \lambda_j^e(a_i) h_j(x|a_i).
$$

(28)

Intuitively, type $a_i$ individuals in employment state $k \in \{e, u\}$ receive opportunities to be employed at firms of type $x$ through channel $j$ at rate

$$
\sum_j \lambda_j^k(a_i) h_j(x|a_i) = -d\Gamma^k(x|a_i).
$$

However, they will only accept and earn a wage $w' \leq w$ if (i) they are hired from unemployment, or (ii) they were employed at a firm of type $x' < x$ such that $w^e(a_i, x', x) \leq w$ or, equivalently, a firm of type $x' \leq \widehat{x}(a_i, x, w)$. Equating the outflow and inflow in equations (27) and (28) yields the result.

For the sake of completeness, here we derive $g(w|a_i, x) = dG(w|a_i, x)$, the density of wages across workers of ability $a_i$ currently employed at productivity $x$. Differentiating (17) yields

$$
g(w|a_i, x) = -\frac{\partial \widehat{x}}{\partial w} \left\{ \frac{\phi^e(\widehat{x}|a_i) d\Gamma^e(x|a_i) [\delta + \Gamma^e(\widehat{x})] - [\phi^u(a_i) d\Gamma^u(x|a_i) + \Phi^e(\widehat{x}|a_i) d\Gamma^e(x|a_i)] d\Gamma^e(\widehat{x})}{\phi^e(a_i, x) [\delta + \Gamma^e(\widehat{x})]^2} \right\},
$$

where

$$
\frac{\partial \widehat{x}}{\partial w} = \frac{r + \delta + \beta \Gamma^e(\widehat{x}|a_i)}{p(1 - \beta) [r + \delta + \Gamma^e(\widehat{x}|a_i)]}.
$$
D Quantitative Exercise

Moments used in the calibration

Here we provide a more detailed description of the sixteen moments we use to calibrate the model.

Unemployment rate. The unemployment rate implied by the model is 
\[ u = \sum_i \phi^u(a_i), \]
where \( \phi^u(a_i) \) characterized in equation (13).

EU rate. The job destruction rate in the continuous time model is simply 
\[ 1 - e^{-\delta}. \]
However, given the relatively high job-finding rate, Shimer (2005) argues that it’s important to account for time aggregation. Hence, we adjust the separation rate to account for time aggregation as Shimer (2005) suggests in equation (2) (on page 32), so that

\[
\text{separation rate} = (1 - e^{-\delta}) (1 - 0.5 \times \text{[job finding rate]})
\]

where the job finding rate is determined endogenously:

\[
\sum_i \Phi^u(a_i) \frac{1}{u} \left[ 1 - e^{-\Gamma^u(x^*_i|a_i)} \right].
\]

EE rate. A worker currently matched at a type \( x \) job moves if and only if he contacts a firm and draws \( x' > x \). Hence, the job-to-job transition rate is:

\[
\sum_i \Phi^e(1|a_i) \frac{1}{1 - u} \left[ 1 - e^{-\Gamma^e(x^*_i|a_i)} \right] \int_{x^*_i}^{\bar{x}} \frac{d\Phi^e(x|a_i)}{\Phi^e(1|a_i)} = \frac{1}{1 - u} \sum_i \int_{x^*_i}^{\bar{x}} \left[ 1 - e^{-\Gamma^e(x|a_i)} \right] d\Phi^e(x|a_i).
\]

Contact rates. The model is silent on whether a meeting between a worker and firm that has a negative surplus (i.e., when \( x < x^*_i \)) should be counted as a “contact.” We adopt the convention that unemployed workers count every meeting as a contact, and hence the average rate at which unemployed workers contact a firm is

\[
\sum_i \phi^u(a_i) \frac{1}{u} \left[ 1 - e^{-\Gamma^u(0|a_i)} \right].
\]

Alternatively, we assume that an employed worker is uninterested in initiating a contact with a new firm if the surplus is negative. Hence, the arrival rate of contacts for employed workers is

\[
\sum_i \Phi^e(1|a_i) \frac{1}{1 - u} \left[ 1 - e^{-\Gamma^e(x^*_i|a_i)} \right].
\]
Residual wage dispersion. Since $G(w|a_i, x)$ denotes the fraction of type $a_i$ who are employed at a firm with match-specific productivity $x$ earning a wage $w' \leq w$, the fraction of all workers earning $w' \leq w$ is

$$\frac{\sum_i \int_{x_i}^x G(w|a_i, x) \phi^e(a_i, x) dx}{1 - u}. $$

Plugging in the closed form expression for $G(w|a_i, x)$ in (17) allows us to calculate the fraction of employed workers earning less than the wages that lie at the 25th and 75th percentiles of the empirical distribution.

Usage across channels. The fraction of employed workers who found their job through channel $j \in \{B, F\}$ is characterized in equation (16).

Average wages across channels. The average wage of employed workers who found their job through channel $j \in \{B, F, O\}$ is characterized in equations (18) and (19).

Average tenure across channels. The average tenure of employed workers who found their job through channel $j \in \{B, F, O\}$ is characterized in equation (20).

Differential usage of channels across the wage distribution. Let $\omega_j(a, x|w)$ denote the cumulative measure of workers of type $a$ who are matched at a firm with productivity $x$ that got their job through channel $j \in \{B, F, O\}$ and currently earn wage $w' \leq w$. In a stationary equilibrium we must have

$$\dot{\omega}_j(a, x|w) = \Phi^e(\hat{x}(a, x, w)|a) d\Gamma^e_j(x|a) + \phi^u(a) d\Gamma^u_j(x|a) 1_{\{w \geq w^u(x,a)\}} - \omega_j(a, x|w) \left[ \delta + \Gamma^e(\hat{x}(a, x, w)|a) \right] = 0. $$

The first line in the expression above captures the inflow of workers into the set. First, a mass $\Phi^e(\hat{x}(a, x, w)|a) d\Gamma^e_j(x|a)$ of type $a$ workers accept offers that arrived through channel $j$ at a job with match-specific productivity $x$ and earn a wage less than or equal to $w$. Second, a mass $\phi^u(a) d\Gamma^u_j(x|a)$ of type $a$ unemployed workers accept an offer that arrived through channel $j$ at a job with match-specific productivity $x$, and hence enter the set if $w \geq w^u(a, x)$. The second line in the expression captures the outflow of workers, who exit either because the match is destroyed or because an offer arrives that increases their current wage above $w$ (either at the incumbent or the poaching firm). Solving yields

$$\omega_j(a, x|w) = \frac{\Phi^e(\hat{x}(a, x, w)|a) d\Gamma^e_j(x|a) + \phi^u(a) d\Gamma^u_j(x|a) 1_{\{w \geq w^u(x,a)\}}}{\delta + \Gamma^e(\hat{x}(a, x, w)|a)}. $$
Using this, the measure of workers earning wage \( w' \leq w \) that got their job through channel \( j \) is:

\[
\Omega_j(w) = \sum_i \int \omega_j(a_i, x|w)dx.
\]

Then the fraction of workers earning \( w' \leq w \) that got their job through channel \( j \) is:

\[
\frac{\Omega_j(w)}{\sum_j \Omega_j(w)}.
\]

To construct the final two moments, we use (29) to calculate the fraction of workers in the top and bottom quartiles of the wage distribution that found their job through channel \( j \in \{B, F\} \), and then we take the difference.

**Parameter Values from Calibration.**

Table 12 reports the parameter values from the calibration.
